We consider the density of states of granular media in which each grain-grain contact is damped with a damping force proportional to the relative velocity of the two grains, in addition to the usual spring constant. Under the assumption that the so-called criterion of proportional damping is only weakly violated we are able to deduce the density of states for undamped frequencies from the measured complex-valued frequencies of damped oscillations. We deduce a quantitative estimate of the deviation from the proportional criterion. We consider, specifically, numerical simulations of cases in which the grains are frictionless spheres which interact via Hertz central forces and all the nonzero contacts are damped with the same damping constant. We show how these ideas can be applied to data on real granular systems.

I. INTRODUCTION

In this article we consider the density of states of granular media in the presence of damping. We develop a theory which, subject to the validity of the assumed approximation, allows one to deduce what the density of states of an undamped system would be, from the measured complex-valued frequencies. The density of states of undamped granular media has received much attention in recent years especially in its connection with the jamming transition [1–6]. Liu, et al. [7] have written a review article on the topic. The idea is that a system jammed under the influence of a static stress induces a static deformation at the grain-grain contacts each of which thus acquires a nonzero stiffness for subsequent small amplitude deformations. One may thereby calculate the normal modes of vibration under the assumption that the system may be in the linear regime of small amplitude vibrations. Such calculations assume the force vs. displacement law for each contact follows from some specific law such as the Hertz/Hertz-Mindlin, or Hooke, or Lennard-Jones laws. Such calculations neglect the effects of damping at the grain-grain contacts. In experiments on real granular media, however, damping can be an important component of the dynamics [8]. Indeed, granular media can very effectively dampen the vibrations of metal structures having grain-filled cavities within themselves (Reference [9] and references therein). Moreover, Reference [8] (and references therein) shows how it is possible to deduce accurate values of the complex-valued normal mode frequencies of a granular aggregate from measurements of the so-called effective mass of the granular medium.

The purpose of the present article is to show how it may be possible to deduce the density of undamped vibrational states of a granular system from the measured complex-valued normal mode frequencies that one has for damped systems. We base our results on our own numerical simulations of damped vibrations in granular media, under stress, in which the grains interact via Hertzian normal forces and via a damping mechanism proportional to the relative velocity of the grain centers. Although the intergranular force is a nonlinear function of contact displacement we linearize around the equilibrium point to compute the normal mode frequencies relevant to small amplitude vibrations.

There are situations in which there is no small amplitude regime whereby strictly linear equations of motion for the departure from equilibrium are valid. Schreck et al. [11] have pointed out that for granular systems interacting via strictly one-sided repulsive forces there is always a distribution of non-contact gaps extending continuously to zero such that in the thermodynamic limit the smallest amplitude of vibration will open and close such a gap which is intrinsically nonlinear. In the present article we assume that in damped granular media this situation does not arise. We assume that the forces of adhesion, adsorption that are the origin of the damping also ensure that each grain-grain contact has a linear operating regime, around the equilibrium configuration.

The article is organized as follows. We describe a general theory of vibrational-libration normal modes of damped granular media in Section II. Here, we also present some relevant exact results as well as a perturbation theory with which we can ultimately compute the undamped density of states. In Section III we describe how we performed our calculations of normal mode frequencies in a system of spherical grains interacting via normal forces, which are damped Hertzian contact forces. The system is compressed under the action of the directional force of gravity. We present our results on the density of states in Section IV. The conclusions are summarized in Section V.

II. THEORY

In this Section we present the assumed general equations of motion whose solutions determine the normal modes of the granular medium. We quote some relevant exact results and we also show the consequences of assuming the proportional approximation for the damping matrix. We end this Section with our derivation of a perturbation theory which we employ to analyze our numerical simulations.

A. General Considerations

Let \( \mathbf{X} \) be the equilibrium position of the center of mass of the i-th particle, whose mass is \( m_i \), and \( \mathbf{u}_i \) be its displacement from equilibrium. Similarly, \( \theta_i \) is the librational angle of rotation. If two neighboring particles translate or rotate such that their points of contact would move relative to each other there will be a restoring force due to the contact forces. The linearized equation of motion for the i-th particle is

\[
-m_i \omega_i^2 \mathbf{u}_i = \sum_j K_{ij} \cdot [\mathbf{u}_j + \theta_j \times \mathbf{d}_{iji} - \mathbf{u}_i - \theta_i \times \mathbf{d}_{iji}] \quad (1)
\]

where \( \mathbf{d}_{iji} \) is the vector from \( \mathbf{X}_i \) to the point of contact with the j-th grain. It is understood that the tensor \( K_{ij}(= K_{ji}) \) is nonzero only for grains actually in contact with each other. (For simplicity we assume there is at most one contact per pair.)

The equation of motion for the angular variables is

\[
-m_i \omega_i^2 I_i \cdot \theta_i = \sum_j d_{iji} \times K_{ij} \cdot [\mathbf{u}_j + \theta_j \times \mathbf{d}_{iji} - \mathbf{u}_i - \theta_i \times \mathbf{d}_{iji}] \quad (2)
\]

where \( I_i \) is the moment of inertia tensor for the i-th particle.

It is understood that, generally, each of the elements of the tensors \( K_{ij} \) is complex-valued and frequency dependent reflecting the microscopic origin of the dissipation. In this article we may take

\[
K_{ij}(\omega) \to K_{ij} - i\omega \xi B_{ij} \quad (3)
\]

in which the second term describes an inter-particle force proportional to the difference in velocity of the two grains. \( K \) and \( B \) are taken as real-valued and frequency independent. The parameter \( \xi \) monitors the strength of the damping. If we think of damping as being controlled by the viscosity of a fluid in the grain-grain contact, \( \xi \) is a stand-in for that viscosity. In this article we investigate how the normal mode frequencies evolve as \( \xi \) is varied. Note that this definition of \( B \) differs slightly from those in References [13] and [14] in that here we explicitly factor out \( \xi \) from the definition.

Eqs. (1) and (2) have non trivial solutions only for specific complex-valued frequencies \( \omega_n \). They may be combined as

\[
[-\omega_n^2 M - i\omega_n \xi B + K] e_n = 0 \quad (4)
\]

where \( e_n \) is the combined vector of normal mode component displacements \( \mathbf{u}_i \) and librations \( \theta_i \). \( M \) is the inertial tensor consisting of either the mass of a grain or the relevant component of the moment of inertia. \( B \) and \( K \) have been suitably generalized to this new notation.

Because the kinetic energy of the grains is always positive the eigenvalues of \( M \) are also all positive. Therefore the matrix \( M^{-1/2} \) can be defined and we can re-write Eq. (4) as

\[
[-\omega_n^2 I + i\omega_n \xi B + \bar{K}] \bar{e}_n = 0 \quad . \quad (5)
\]

Here we have defined: \( \bar{e}_n = M^{1/2} e_n \), \( \bar{B} \equiv M^{-1/2} B M^{-1/2} \) and \( \bar{K} \equiv M^{-1/2} B M^{-1/2} \).

Next, we investigate the trajectories of the normal mode frequencies, \( \omega_n \), as the damping parameter \( \xi \) is varied \( \omega_n = \omega_n(\xi) \). Regardless the value of \( \xi > 0 \) the imaginary part of any normal mode frequency is always negative, \( \Im(\omega_n(\xi)) < 0 \), corresponding to a mode which exponentially decays in time. Moreover, for every underdamped normal mode frequency in the 4th quadrant, \( \omega_n^* \), there is another in the 3rd quadrant \( \omega_n = -(\omega_n^*)^* \), where \( * \) signifies complex-conjugation, which is obvious from the structure of Eqs. (4). There may also be overdamped normal modes for which \( \omega_n^* \) are imaginary valued.

B. Exact Results

If there is no damping, \( \xi = 0 \), then the real symmetric matrix \( K \) has positive eigenvalues \( \omega_n^0 \) and the undamped frequencies of oscillation for the corresponding normal modes \( e_n^0 \) are \( \pm \omega_n^0 \). For small enough values of the damping one may do 1st order perturbation theory with the result [8]:

\[
\omega_n^\pm = \pm \omega_n^0 - \frac{\xi}{2} \frac{\bar{e}_n^0 \bar{B} e_n^0}{\bar{e}_n^0 \bar{e}_n^0} + O(\xi^2) \quad . \quad (6)
\]

Each normal mode frequency initially moves perpendicular to the real axis from its starting point on the real axis.

For each trajectory, \( \omega_n(\xi) \), there exists a critical value \( \xi_{nc} \), which is finite, such that the mode becomes critically damped i.e. \( \omega_n \) is purely imaginary. For values of \( \xi \) approaching \( \xi_{nc} \) one has [13]

\[
\lim_{\xi \to \xi_{nc}} \omega_n^\pm(\xi) = -i \lambda_n \geq g_n(\xi_{nc} - \xi)^{1/2} + O(\xi - \xi_{nc}) \quad , \quad (7)
\]

where \( \lambda_n \) and \( g_n \) are positive real numbers. Thus, the two branches \( \omega_n^\pm(\xi) \) coalesce onto a single value on the negative imaginary axis at the critical damping. Their approach to \( -i \lambda_n \) as \( \xi \to \xi_{nc} \) is perpendicular to that axis. As \( \xi \) increases above the critical value the two roots remain imaginary and move apart from \( -i \lambda_n \).

C. Proportional Damping

In the very special case known as proportional damping [12] the matrix of damping parameters, \( B \), is everywhere proportional to the matrix of stiffness constants, \( K \). We may subsume this proportionality constant into the definition of \( \xi \) and write:

\[
\bar{B} = \bar{K} \quad . \quad (8)
\]

If Eq. (8) holds true then the solution to Eq. (5) is simple. Because \( e_n^0 \) is now an eigenmode of \( B \) it is also an eigenmode of the entire problem. The result is

\[
\omega_n^\pm(\xi) = \frac{-i \xi \omega_n^0}{2} \pm \omega_n^0 \sqrt{1 - \left( \frac{\xi \omega_n^0}{2} \right)^2} \quad . \quad (9)
\]
This well-known result obeys the exact results presented in the previous subsection. One has \( \xi_{nc} = \frac{2}{\omega_0} \).

The trajectories of the normal modes under the condition of proportional damping are perfect circles with center at the origin up to the point each becomes overdamped:

\[
| \omega_n^\pm(\xi) | = \omega_0 \quad \forall \xi \leq \xi_{nc} = \frac{2}{\omega_0} \quad (10)
\]

Moreover the locus of all the (underdamped) normal mode frequencies for a given value of \( \xi \) is also a circle. The radius is \( 1/\xi \) and the center is at \(-i/\xi\) [8, 13]:

\[
| \omega_n^\pm(\xi) + i/\xi | = 1/\xi \quad \forall n \text{ s.t. } \xi \leq \xi_{nc} = \frac{2}{\omega_0} \quad (11)
\]

D. Perturbation Theory

We now consider a situation, relevant to our numerical results, in which the proportional damping criterion, Eq. (8), is approximately true in the sense that departures from it are small:

\[
\mathbf{B} = \mathbf{K} + \Delta \mathbf{B} \quad (12)
\]

We consider the effects of \( \Delta \mathbf{B} \) to 1st order in perturbation theory. We make the substitutions \( \mathbf{e}_{0n} \to \mathbf{e}_{0n} + \Delta \mathbf{e}_{0n} \), \( \omega_n(\xi) \to \omega_n(\xi) + \Delta \omega_n(\xi) \) in Eq. (4) or, equivalently, (5) and collect all the terms which are 1st order in \( \Delta \mathbf{B} \). We have

\[
0 = (-\omega_n^2 + i\omega_n \xi \mathbf{K} + \Delta \mathbf{K}) \Delta \mathbf{e}_{0n} + \Delta \omega_n(\xi) \mathbf{e}_{0n} - i\omega_n \xi \Delta \mathbf{B} \mathbf{e}_{0n} \quad (13)
\]

Because the matrix \( \mathbf{K} \) is real-symmetric so is \( \Delta \mathbf{K} \) which means that \( \mathbf{e}_{0n}^T \) is a left eigenvector of \( \Delta \mathbf{K} \), having the same eigenvalue, \( \omega_n^2 \). If we multiply Eq. (13) on the left by \( \mathbf{e}_{0n}^T \) the first term on the RHS vanishes identically and we have our desired result:

\[
\Delta \omega_n^\pm(\xi) = \frac{i\omega_n^\pm(\xi) \xi \Delta \mathbf{B}_{nn}^2}{2\omega_n^2(\xi) + i\xi \omega_n^2} + \mathcal{O}(\Delta \mathbf{B})^2 \quad (14)
\]

where

\[
\Delta \mathbf{B}_{nn} = \frac{\mathbf{e}_{0n}^T \Delta \mathbf{B} \mathbf{e}_{0n}}{\mathbf{e}_{0n}^T \mathbf{e}_{0n}} \quad (15)
\]

With the use of Eq. (9) we may re-write this in the form

\[
\Delta \omega_n^\pm(\xi) = i\omega_n(\xi) \Delta \theta_n^\pm \quad (16)
\]

where

\[
\Delta \theta_n^\pm(\xi) = \mp \frac{\xi \Delta \mathbf{B}_{nn}}{2\omega_0 \sqrt{1 - (\xi \omega_n^2)^2}} \quad (17)
\]

Eqs. (16) and (17) show that to 1st order in \( \Delta \mathbf{B} \) the normal mode frequency moves by an angular amount \( \Delta \theta_n^\pm \) along the same circular trajectory defined by Eq. (10):

\[
| \omega_n^\pm(\xi) + \Delta \omega_n^\pm(\xi) | = \omega_0 + \mathcal{O}(\Delta \mathbf{B})^2 \quad (18)
\]

We shall use Eq. (18) to deduce information about the distribution of undamped frequencies \( \omega_n \) from our data in the presence of damping under the assumption that deviations from the proportional damping criterion are weak.

FIG. 1: (Color online) The complex-valued normal mode frequencies of the model granular medium for different values of the damping parameter, \( \xi \). The legend gives the values of \( 2\pi \xi \) in milliseconds. The solid curves are circles of radius \( 1/(2\pi \xi) \) as per Eq. (11). The dashed lines are the trajectories of three of the normal mode frequencies as \( \xi \) is increased from zero to \( \xi_{nc} \) and beyond. All the modes are underdamped for the smallest three values of \( \xi \) whereas for the others some of the modes are overdamped.

III. NUMERICAL SIMULATIONS

In previous publications [13, 14] we reported the results of normal mode calculations of ensembles of granular media confined to a container. Our interests were to gain some understanding of the properties of the so-called effective mass of granular media [8, 10]. Accordingly, the particles in the simulations were not subjected to an isotropic confining pressure but, rather, they were subjected to a directional gravitational field, as per the experiments. The particles were identical spheres of mass \( m \). We assumed the particles were frictionless and that they interact with their neighbors via the Hertz force [15]:

\[
F_N = \frac{2}{3} k_r R^{1/2} x_{ij}^{3/2} \quad (19)
\]

where \( R \) is the radius and \( x_{ij} > 0 \) is the degree of compression of the center-to-center distance between sphere \( i \) and sphere \( j \). (There is no force between non-contacting spheres.) After the spheres have settled into their equilibrium configuration each contact has a different value of the static compression
\( x_{ij} \), those near the top of the container are compressed less than those near the bottom. Each contact responds to an infinitesimal additional distortion by means of a spring constant which is given by
\[
\frac{dF_N}{dx_{ij}} = k_nR^{1/2}x_{ij}^{1/2}.
\]
(20)

In tensor notation, then, the expression for the 3 x 3 stiffness matrix between two contacting spheres is
\[
K_{ij} = k^N(x_{ij})\mathbf{d}_{ij}\mathbf{d}_{ij},
\]
(21)
where \( \mathbf{d}_{ij} \) is a unit vector pointing from one sphere center to the other and we are using dyadic notation.

We assumed the damping matrix \( \mathbf{B} \) is of the same general form as Eq. (21) except that we assumed all the damping constants were the same for any two spheres in contact.

\[
\mathbf{B}_{ij} = \langle k^N \rangle \mathbf{d}_{ij}\mathbf{d}_{ij},
\]
(22)
where \( \langle k^N \rangle \) is the average of all the nonzero \( k^N(x_{ij}) \) values.

The motivation behind this assumption was that we were attempting to understand the damping effects of adsorbed fluids at the grain-grain contacts which are presumably insensitive to the degree of compression of the two grains. The complex-valued resonance frequencies of Eq. (4) are now computed from the eigenvalues \( \{\lambda_n\} \) of the matrix \( \mathbf{A} \) which is given in block form as
\[
\mathbf{A} = \begin{pmatrix} 0 & \mathbf{I} \\ -\mathbf{M}^{-1}\mathbf{K} & -\xi\mathbf{M}^{-1}\mathbf{B} \end{pmatrix}.
\]
(23)

We have \( \omega_n = i\lambda_n \). More details of the simulations may be found in References [13] or [14].

The results of our simulations, for different assumed values of \( \xi \), are shown in Figure 1 for a situation in which we simulated 314 spheres, giving rise to 1884 normal mode frequencies, the underdamped of which occur as pairs in the 3rd and 4th quadrant. Of these 1884 normal mode frequencies 22 of them are essentially zero frequency modes (< 3 x 10^7Hz in absolute value), which we do not include in the analysis. It is clear that \( \mathbf{B} \neq \mathbf{K} \). Nonetheless the consequences of Eq. (8) are reasonably well attained. Each trajectory is roughly a circle as per Eq. (10) and each obeys the exact results Eqs. (6) and (7). The loci of all the frequencies is also approximately a circle, Eq. (11). All of the modes are underdamped for the three smallest values of \( \xi \). Some of the modes are overdamped (\( \omega_n \) is purely imaginary) for the other three values of \( \xi \). (See the Supplemental Material [16] for a movie which shows the evolution of all the complex frequencies as \( \xi \) is continuously increased starting from zero.) The data lend themselves to an analysis with the perturbation theory described in Section II D.

\section{IV. DENSITY OF STATES}

Assuming the approximate validity of Eq. (18) it is easy to compute the density of undamped states, \( N(\omega_{n0}) \), from the measured underdamped frequencies. The number of states which would have an undamped frequency between \( \omega_{n0} \) and \( \omega_{n0} + \Delta\omega_{n0} \) is equal to the number of actual modes for which \( \mid \omega_n \mid \) lies within these limits, for the underdamped modes. Corrections to this are of order \( O(\Delta\mathbf{B})^2 \). We have binned all the underdamped frequencies shown in Figure 1 accordingly. The results are shown in Figure 2. For the three smallest values of \( \xi \) all of the normal modes are underdamped and the resultant density of states for each of these data sets agrees with the others. The partial density of states computed from the simulations corresponding to the three largest values of \( \xi \) are also in agreement with the other three. This agreement is due, evidently, to the perturbation theory result, Eq. (18).

We note that our results for the undamped density of states do not exhibit the well-known low frequency plateau characteristic of the density of states in jammed systems reported by others [1–7]. We attribute this to the several differences between our calculations and theirs. Our system is not intended to model a macroscopically infinite system. Rather, we are modeling the normal modes of a rigid cup, loosely filled with grains. There is a rigid bottom plane and the top has a finite extent. Two of the side walls are also rigid; the remaining direction has periodic boundary conditions. Perhaps the most obvious difference is that we have included a constant downward force on each sphere, intended to mimic the force of gravity. Thus, the spheres toward the bottom are compressed more than those near the top and the system is macroscopically heterogeneous. So to say, the distance from the so-called J point varies continuously from top to bottom.

At this point we may push our luck and compute the contribution to the densities of undamped states from all the overdamped states i.e. those on the negative imaginary axis. From Eq. (9) we have
\[
\xi > \xi_{nc} \Rightarrow \omega_n^\alpha(\xi) \propto \frac{\xi\omega_{n0}^2}{2} + \omega_{n0} \sqrt{\left( \frac{\xi\omega_{n0}}{2} \right)^2 + O(\Delta\mathbf{B})^1},
\]
(24)
which can be inverted:
\[
\omega_{n0} = \frac{\mid \omega_n^\alpha(\xi) \mid}{\sqrt{\xi} \mid \omega_n^\xi(\xi) \mid} + O(\Delta\mathbf{B})^1.
\]
(25)
The overdamped modal frequencies order as \( \mid \omega_n^\alpha(\xi) \mid \ll 2/\xi \ll \omega_n^\xi(\xi) \). We convert each value of \( \mid \omega_n^\alpha(\xi) \mid \) into its undamped value according to Eq. (25) and compute the contributions of these frequencies to a partial density of states. The results for the three data sets which have overdamped modes are shown in Fig. 3. They agree with each other for frequencies \( \omega_{n0} > 2/\xi \). This is quite surprising because Eq. (24) has errors of order \( (\Delta\mathbf{B})^1 \), unlike Eq. (18).

Pushing our luck further again we plot the total density of states \( N_{total} = N + N_{overdamped} \) in Figure 4. Remarkably, all six data sets, corresponding to damping parameters \( \xi \) which range over a factor of 2000, stack on top of each other. We conclude that we have identified a way to deduce the density of undamped states from measurements of those states which are possibly heavily damped.

Finally, we use Eq. (17) to deduce some information about the degree to which the proportional damping condition, Eq.
(8), is violated. The situation is demonstrated graphically in Figure 5 where we have highlighted one datum for analysis. Were the proportional damping criterion to hold exactly this point would lie on the intersection of the two circles given by Eq. (10) (the dashed curve) and Eq. (11) (the solid curve). (For some of the underdamped frequencies the two curves do not intersect and are excluded from the analysis.) The angular deviation, $\Delta \theta_n$, between this point and the actual location is related to the deviation from the proportional criterion by Eq. (18), to 1st order. It is simple enough to solve for $\Delta \mathbf{B}_{mn}$ for each data point. The results are plotted in Figure 6 as a function of the presumed value of $\omega_{\|0}$ for each trajectory, for each of the six data sets.

We have plotted the results for the three least damped systems in the top panel; the other three are plotted in the bottom panel. There are several interesting features to these results. First, we see that the results for $2\pi \xi = 0.0008$ and $2\pi \xi = 0.008$ virtually overlie each other. That for $2\pi \xi = 0.08$ is consistent with these two but has a larger spread in apparent $\Delta \mathbf{B}_{mn}$ values. This may indicate the breakdown of the 1st order perturbation theory, though we have already seen that the density of states calculation is still robust. The spread is noticeably smaller for $\omega_{\|0}$ less than 5kHz in all three data sets. There is a noticeable systematic variation of $\Delta \mathbf{B}_{mn}$ with $\omega_{\|0}$ in all three sets.

The situation is significantly different for the case of the three largest values of the damping parameter, $\xi$, which are shown in the lower panel of Figure 6. Obviously, only those underdamped modes for which the two circles, Eqs. (10) and (11), have an intersection are those which can be analyzed. Even so it is surprising to us that the surviving values of $\Delta \mathbf{B}_{mn}$ are so much smaller than those in the top panel of the figure. In almost all cases we have $\mathbf{B}_{mn} \ll \mathbf{K}_{mn} = \omega_{\|}^2$ as would be a necessary condition for the validity of first order perturbation theory.

We note, however, from Eq. (9) that there is a simple relation between the polar angle, $\theta_m$, and the damping parameter, $\xi$, when the proportional damping criterion holds:

$$\sin(\theta_m^*) = -\frac{\xi \omega_{\|0}}{2}.$$  \hspace{1cm} (26)

This, in turn, implies $\theta_m^*(\xi) \to -\pi/2$ with infinite slope as $\xi \to \xi_{cc} = 2/\omega_{\|0}$. But Eq. (17) indicates that corrections to Eq. (26) due to the breakdown of the proportional damping approximation themselves diverge in this limit. Thus, a more appropriate condition for the validity of 1st order perturbation theory might be the more restrictive relation $|\frac{d\Delta \mathbf{B}_{mn}}{d\xi}| \ll |\frac{d\mathbf{B}_{mn}}{d\xi}|$. This restriction would imply that the validity of Eq. (17)
should be restricted to $\xi \ll \xi_{nc}$. We see from Eq. (17) that solving for $B_{m}$ from the measured $\Delta \theta_n$ values will tend to collapse $B_{m}$ to small values, for heavily damped systems.

It is clear from Figure 5 and Eq. (17) that if $\Delta B_{m}$ is large enough the computed $\Delta \theta_n$ would mean the resonance frequency would lie on the negative imaginary axis. For larger values of $\Delta B_{m}$ the modes would be overdamped and Eq. (17) would be meaningless. These boundaries are indicated with the dashed lines in Figure 6.

These ideas can, at least in principle, be applied to real experimental data on granular systems. If the number of measurable frequencies is large enough a cross-plot of those frequencies in the complex plane could allow one to deduce the approximate value of $\xi$, assuming the proportional damping model has approximate validity. This was partially accomplished in Figure 7 of Reference [13] in which previously published experimental data were shown to cluster around the circle defined by Eq. (11), although the existing data covered only a small fraction of that circle. The contribution to the undamped density of states from the underdamped modes does not require a knowledge of $\xi$ but the contribution from the overdamped modes does require it as does any estimate of the deviation, $\Delta B_{m}$, from the proportional damping criterion.

\caption{(Color online) Total density of states of the modes whose complex-valued frequencies are shown in Figure 1. Each curve is the sum of the relevant curves in Figures 2 and 3. These six curves are essentially all the same.}
\end{figure}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure5.png}
\caption{(Color online) Graphical illustration of $\Delta \theta_n$. The data set corresponds to $2\pi \xi = 0.4$ and one of those data points is isolated. The dashed curve is a circle of radius $|\omega_n|$ passing through that point. The solid curve is a circle of radius $(2\pi \xi)^{-1}$ as per Eq. (11). The difference between the actual location of the normal mode frequency and the intersection of these two circles defines $\Delta \theta_n$, as indicated. In this example $\Delta \theta_n < 0$.}
\end{figure}

V. CONCLUSIONS

We have presented a way of analyzing normal mode frequencies of granular media in situations where these frequencies are complex-valued due to damping. We have argued that in cases in which the so-called proportional damping criterion is weakly violated one may reconstruct the density of undamped states from the measured complex-valued frequencies. Furthermore, we have shown how one may deduce specific information about the relevant matrix elements of the damping matrix that relate to deviations from strictly proportional behavior. The ideas presented here work reasonably well on numerical simulations of the normal modes of a collection of spheres interacting via Hertz contacts for the stiffness and with the assumption that all the contacts are damped the same. We have shown how these ideas can be applied to data on real granular systems, assuming one is able to measure a significant number of those frequencies.
FIG. 6: (Color online) Deduced values of $\Delta B_m$ cross-plotted against $|\omega_m| = \omega_{\omega_0}$. (a) The lowest three values of damping, $\xi$, for which all the modes are underdamped. (b) The remaining three values of $\xi$ for which some of the modes are overdamped. For these data sets we can deduce $\Delta B_m$ only for the underdamped of those modes. Note the change of scale in the axes for the two plots. The dashed curves demonstrate the maximum value of $\Delta B_m$ that can be deduced with our technique.

We thank NSF (Grant DMR-1308235) and DOE Geosciences Division (Grant DE-FG02-03ER15458) for financial support.

[16] See the Supplemental Material at http://link.aps??? for a movie which shows how the normal mode frequencies evolve as $\xi$ is continuously increased, starting from zero. For any value of $\xi$ the red symbols indicate the corresponding eigen-frequency and the blue symbols indicate all the frequencies for the previous values of $\xi$. Thus one may see all the trajectories of all the modes, in the complex plane.
